ABSTRACT

The purpose was to assess the isokinetic strength adaptations of eccentric knee flexors (eccKF) and concentric knee extensors (conKE) in a professional male soccer player during anterior cruciate ligament (ACL) rehabilitation. Progress was monitored relative to a non-injured control group. Isokinetic strength assessments were initiated 18 weeks post ACL reconstruction and

comprised assessments at eight angular velocities between 60 and 270°·s⁻¹. The assessments ceased at the point where the player was cleared for return to play 6 months after reconstructive surgery by his club. The results identified that conKE peak torque of the treatment limb and eccKF peak torque of both lower limbs demonstrated meaningful changes. In addition, the eccKF angle of peak torque also demonstrated meaningful change that occurred at increased knee extension. The inclusion of additional angular velocities and angle specific measures provide new insight into rehabilitation and return to play.

Key words: Knee injury, strength profiling, soccer, hamstring, quadriceps

Key points:

- Angle specific isokinetic strength assessments should be conducted at varying angular velocities at the point of return to play.
- Isokinetic assessments should consider an angle specific function strength ratio at the point of return to play.
- The slope of the force-velocity curve is changeable through rehabilitation

INTRODUCTION

A study in professional male soccer reported that only 65% of players who sustain an anterior cruciate ligament (ACL) injury return to previous competitive levels three years after injury.¹ Secondary ACL injuries are also common amongst professional soccer players, attributed to strength impairments of knee flexor (KF) and extensor (KE) musculature at the point of return

to play.^{2,3} Given the functional role in stabilising the knee,⁴ adaptation of the KF and KE musculature during rehabilitation is of primary importance.

Isokinetic assessments of concentric KF and KE strength are used to identify rehabilitation responses and bilateral asymmetry at the point of return to play.^{5,6} However, failure to consider the functional eccKF:conKE ratio⁷ and slow testing velocities in relation to injury mechanism limits functional interpretation. Specifically, ACL injury risk is associated with lower functional eccKF:conKE ratio's that indicate higher KE strength relative to the KF musculature, thereby increasing ACL strain.⁸ As functional movements associated with ACL injury^{9,10} exhibit increased knee angular velocities¹¹, isokinetic strength assessments should therefore be characterised by KF and KE at similar testing velocities. Furthermore, whilst isokinetic assessment of KF and KE strength is common within professional soccer,¹² the sole use of functional eccKF:conKE ratio fails to consider that KF and KE peak torques (PT) occur at different knee joint angles.¹³ When considering the injury mechanisms associated with ACL injury,^{14,15} angle specific strength measures should be considered at relevant knee extension angles and angular velocities

A common return to play criteria in professional soccer assesses bilateral strength asymmetry of both the injured and non-injured lower limbs, where values less than 10% are considered acceptable.⁸ However, following a prolonged rehabilitation period, the detrained and atrophied non-injured limb may not represent a suitable control. Therefore, a healthy control group may be used to help identify whether strength deficits exist in injured populations.⁶ Return to play guidelines also suggest KE strength asymmetries greater than 10% and returning to play before 9

months postoperative surgery are significant predictors of ACL re-injury,⁸ thus reiterating the importance of sufficient rehabilitation. The primary aim of this study was to observe changes in a professional soccer player's isokinetic bilateral strength at varying angular velocities during late stage rehabilitation from ACL reconstructive surgery. A second aim of the study was to compare these data to that of a healthy control group. The final aim of this study was to consider both angle specific and non-angle specific strength ratios at the point of return to play. **Case**

Presentation

Patient

The case was a 26 year-old professional male soccer player (height: 184.50cm; mass: 84.50 kg) from the English Football League Division Two. The injury occurred in January 2016 during a contact situation where the case collided with an opponent attempting a tackle, injuring the dominant right lower limb (defined as the preferred kicking limb).¹³ The present injury occurred during the first 15 minutes of a match. The ACL injury was confirmed by a magnetic resonance imaging scan, revealing a grade III tear. Surgical reconstruction of the right ACL was performed via patella tendon graft 7 weeks after injury. An injury also occurred to the medial collateral ligament (MCL) with a grade III tear to the right lower limb ~5 months prior to the present injury. The case has also previously injured their left ACL ~8 years prior to the present injury. A hamstring tendon was used to reconstruct their left ACL.

Intervention

During the first visit to the laboratory, case and club consent were obtained for the assessment of isokinetic (System 4, Biodex Medical Systems, New York, USA) eccentric KR

(eccKE) and concentric KE (conKE) strength from 18 weeks post ACL reconstruction to return to plat. To replicate the club training times¹⁶ testing was conducted between 1000-1200 hours over five trials, comprising one familiarisation trial and four isokinetic strength assessments interspersed by two weeks. Before each trial, a standardised 5 minute warm-up on a stationary cycle ergometer was completed (Monark, 824E, Sweden) at 60W.

Bilateral isokinetic strength of eccKF and conKE were completed at eight angular velocities completed in the order of 150, 180, 120, 210, 90, 240, 60 and 270°·s⁻¹.¹⁷ At each angular velocity, the case was instructed to exert maximal effort for 3 repetitions, with no performance feedback.^{12,18} The dynamometer setup was adjusted specifically for the participant in line with the manufacturer’s guidelines, with the cuff of the lever arm secured around the ankle proximal to the malleoli. The case was secured in a seated position with the hip positioned at approximately 90°. Restraints were applied proximal to the knee joint across the thigh, waist and chest. The repetition eliciting the highest PT was further analysed to quantify the corresponding angle of peak torque (APT) and the slope of the force-velocity curve (M)¹⁹:

$$M = (\text{Torque}[Y2 - Y1]) / (\text{Angular Velocity}[X2 - X1])$$

The M value quantified the slope of the force-velocity curve by each PT value for eccKF and conKE contractions across angular velocities (i.e. Y2 and X2 referred to PT data at 270°·s⁻¹, whereas Y1 and X1 referred to PT data recorded at 60°·s⁻¹). The M value was used to describe the slope of the force-velocity curve for the respective musculature. Strength ratios were defined as the eccKF:conKE ratio⁷ derived from the peak eccKF and conKE values. When considering that ACL injuries have previously been reported to occur when the shank is in a more extended

position,^{9,14} the strength ratios (angle specific eccKF:conKE ratio) were also calculated from torque data recorded at the angle of maximal knee extension (40° of knee flexion) common to all testing velocities. A rehabilitation response was determined by comparing the data recorded for both the treatment and uninvolved limbs across weeks of the rehabilitation. The within-subject standard deviation for all four assessments were used to calculate standard error of measurement (SEM),²⁰ with bilateral changes greater than the SEM being regarded as meaningful.²¹ To determine a treatment effect, the data recorded from the initial assessment (week 18) was compared to that at the point where the club decided the player was returning to play (week 24). Where appropriate, both the rehabilitation and treatment effects were quantified using both absolute and relative differences.

In addition to the aforementioned analyses, the final isokinetic strength assessment (week 24) was compared to a control group of 26 male soccer players (age 26.19 ± 4.65 years; height 181.65 ± 5.71 cm; mass 82.19 ± 9.01 kg) who were injury free ≥ 6 months, prior to data collection. All players within the control group had no previous history of surgery or trauma to the knee. The control group were recruited from the same team to control for differences in training. The control group data comprised average PT, APT, and the eccKF:conKE ratio data recorded from isokinetic bilateral strength assessments of the eccKF and conKE musculature at angular velocities of 180, 270 and $60^\circ \cdot s^{-1}$.

Comparative outcomes

Tables 1 and 2 summarise the biweekly rehabilitation responses for the uninvolved and treatment limbs during the assessment period. At the initial assessment (Week 18), bilateral

differences in eccKF PT were greater than the SEM at only 150-180°·s⁻¹ (Table 1). By Week 24 the bilateral difference in PT was smaller than the SEM at all testing velocities (Table 1). In contrast, the initial assessment at Week 18 revealed that bilateral differences in conKE PT were greater than the SEM at all testing velocities (Table 2). This bilateral difference was maintained throughout the rehabilitation period, with the bilateral difference less than the SEM at Week 24 only at the highest testing velocity of 270°·s⁻¹.

Table 3 summarises the overall treatment effect during the rehabilitation period. Meaningful changes (greater than SEM) were achieved in eccKF PT at all velocities for the treatment limb, and all velocities except 150-180°·s⁻¹ in the uninvolved limb. The treatment limb also showed a meaningful change in eccKF APT at all velocities except 210°·s⁻¹ and 270°·s⁻¹. Meaningful changes in eccKF APT in the uninvolved limb were observed at 90°·s⁻¹ and 210-270°·s⁻¹. In conKE PT, meaningful changes were evident at all velocities in the treatment limb, whilst no meaningful changes were observed in the uninvolved limb. The APT data recorded for the treatment limb's conKE data also identified a meaningful effect at all angular velocities except 120°·s⁻¹ and 240°·s⁻¹. The uninvolved limb showed a meaningful change in conKE APT only 12 at 60°·s⁻¹ and 180°·s⁻¹.

In relation to the additional analyses, it was also identified that the eccKF and conKE slopes (as determined by the *M* values) decreased and increased respectively during the rehabilitation period. Table 4 identifies differences between the eccKF:conKE ratio and angle specific eccKF:conKE ratio data at the point of return to play, with increased angle specific eccKF:conKE ratios (40° knee flexion) being identified for both the uninvolved and treatment limbs.

The control group PT values (normalised to body mass) are illustrated in Figure 1. At return to play, conKE PT data recorded for the uninvolved limb was within 10% of that elicited from the control group. The conKE PT data recorded for the treatment limb was lower when compared to the mean data, but were within the range of the control group (Figure 1). As identified in Figure 1, the eccKF PT data recorded across both of the case's limbs were similar to that of the control group. Due to the observed strength deficits in the conKE musculature, the eccKF:conKE ratio for the treatment limb were greater than both the uninvolved limb and the control group (Figure 2).

DISCUSSION

The aims of this study were threefold. Firstly, to quantify the strength characteristics of the eccKF and conKE musculature across a range of angular velocities during late stage ACL rehabilitation in a professional soccer player. Secondly, to compare these data to that of a healthy control group. Thirdly, to consider both angle specific and non-angle specific strength ratios at the point of return to play.

Typically practitioners identify strength asymmetries between injured and non-injured limbs, forming part of return to play criteria.⁸ However, the use of bilateral asymmetries are not entirely appropriate as detraining effects can also occur in a non-injured limb.⁵ In relation to the first aim, at week 18 large bilateral differences were observed across all angular velocities for both the eccKF and conKE musculature. The bilateral differences did fluctuate throughout the rehabilitation period; however, lower bilateral differences were consistently identified for the eccKF data, with differences lower than the SEM identified at the final assessment. The conKE data however elicited a response whereby the bilateral differences were consistently greater than

those associated with the eccKF data, and at the final assessment, the observed differences were greater than the SEM. When considering the role of the KE musculature in relation to knee stability,¹⁴ these data therefore suggest that at the point of return to play, the player may be at an increased risk of re-injury.^{2,3,8} Consequently, practitioners should monitor and focus on restoring conKE strength after an ACL injury. Especially when considering that the current rehabilitation programme appears to be insufficient to develop the PT of the conKE musculature. It should however be acknowledged that for the current case, the club deemed the player to be ready to return to play even with the knowledge of these data.

When considering the previous criticisms of bilateral comparisons to inform return to play decisions,⁵ an alternative method is to compare the data recorded from the injured player to that of a non-injured control group. This was considered in relation to the second aim of the study, with the conKE and eccKF PT data recorded for both limbs being within the range of the control group. These data therefore suggest that relative to a non-injured population, the case possessed sufficient thigh muscular strength characteristics, thus suggesting they may be appropriately adapted to return to play. The current data did however identify that the eccKF: conKE ratio was considerably larger for the treatment limb when compared to both the uninvolved limb and the control group's data. This response is a result of the impaired conKE musculature identified at the point of return to play, and further advocates the use of a number of strength characteristics to determine a player's readiness to return to play. Furthermore, when considering the aforementioned bilateral differences identified across the rehabilitation period, these data also support the use of a number of methods to inform return to play decisions.

The rehabilitation responses for the treatment limb identified large changes in PT for both the eccKF and conKE musculature at all angular velocities, with direct influence on the force velocity slopes. Specifically, improvements were identified across all velocities; however, these improvements did elicit a trend for a reduced absolute magnitude change as a main effect for increased velocity. As such, although the M value increased for the conKE data of the treatment limb, the observed change in the slope was small due to the somewhat similar upwards shift in torque identified for all testing velocities. The slope of the eccKF PT recorded across the angular velocities decreased during the rehabilitation period for both lower limbs. As such, the eccKF slope at the point of return to play better resembled that previously observed in non-injured players, whereby more consistent PT is observed across all testing velocities.²² These novel findings suggest that the force-velocity slope is modifiable through rehabilitation and training, with this response being relative to both the muscle group and contraction type. These data therefore have potential implication for exercise prescription and training adaptation monitoring.

Although the changes in conKE APT were variable in both lower limbs during the assessment period, APT of eccKF demonstrated large changes with greater force production at increased knee extension angles. The observed shift of eccKF PT towards increased knee extension suggests that the KF musculature may better conditioned to stabilise the knee joint at those angles associated with ACL injury.¹⁴ These data therefore identify the importance of including a number of isokinetic metrics when analysing training induced changes in strength characteristics.

The calculation of the eccKF:conKE ratio is typically performed using peak torque data without consideration that eccKF and conKE peak at different knee joint angles.⁷ These ratios

therefore negate consideration of angle matched torques, and also the consideration of ipsilateral imbalances in an extended position, where ACL injuries have previously been identified to most likely occur.¹⁴ Previous studies have therefore attempted to assess angle specific eccKF:conKE ratios in soccer players, with a consensus that these players typically possess increased eccKF torque towards more extended knee angles when compared to the conKE musculature. This is supported by the current data, whereby the angle specific eccKF:conKE ratio values were notably higher in the treatment limb, as a result of impaired conKE torque at increased knee extension angles across all testing velocities. This response was not however observed to the same magnitude for the non-angle specific eccKF:conKE strength ratio. These data therefore reiterate the importance of ensuring the conKE musculature possesses sufficient strength at more extended knee angles, and raises questions about the use of non-angle specific strength ratios as a means of determining return to play.

Clinical Bottom Line

This present study provides insight into how the strength characteristics of the eccKF and conKE musculature adapted to late stage ACL rehabilitation in a professional male soccer player. It was identified that at the point of return to play, bilateral differences were identified for the conKE data recorded from the case's treatment limb, with potential implications for an increased risk of injury.^{2,3,8} In contrast to this, irrespective of limb, the conKE and eccKF PT data was identified to be within the range associated with a non-injured control group. Observed changes were also identified for the eccKF APT data as a result of the rehabilitation process, thus suggesting the ability to modify this metric through training. The observed response was for eccKF

PT to occur in a more extended knee position, thus potentially offering a protective mechanism to future ACL injury risk. An additional novel consideration of the current study was to quantify the force-velocity slope as a method of assessing the rehabilitation response. This method could be considered for future work to provide a single number to quantify the shift in this slope, thus providing an understanding of the velocity dependent training response. The final consideration of the current study was to compare both angle specific and non-angle specific strength ratios. The current data identified that strength ratios towards a more extended knee angle identified large ipsilateral strength deficits that were not of the same magnitude with the non-angle specific ratios. These data therefore support the use of ipsilateral, bilateral, and between group comparisons and the use of a number of strength metrics to better inform return to play decision-making.

Abbreviations: APT = angle of peak torque; conKE = concentric knee extensors; M = force-velocity curve; PT = peak torque.

The treatment effect for the PT and APT data recorded for the eccKF and conKE musculature of the uninvolved and treatment limbs. A negative PT value indicates a reduction during the 6 week period. A negative APT value indicates a change towards more extended knee angle.
